Abstract

The behavior of stock prices has been studied extensively throughout the last century, and contradictory results have been reported in the corresponding literature. In this paper, we provide another perspective using a network theoretical approach to investigate how crises affected the behavior of US stock prices. We analyze high frequency data from S&P500 via the Horizontal Visibility Graph method, and find that all major crises that took place in the last twenty years, worldwide, affected significantly the behavior of the price-index. Nevertheless, we observe that each of those crises impacted the index in a different way or with a different magnitude. Interestingly, our results suggest that the predictability of the price-index series increases during the periods of crises.

Keywords: S&P500 index, high frequency data, horizontal visibility graph, chaos theory, irreversibility, financial crises

1. Introduction

For many decades now, there is an increasing interest in both academia and the financial industry regarding the extent to which the stock's price history can assist to understand the behavior of its future prices. Particularly, throughout the
5 previous century, various *chartist* theories were proposed which assume that the past

behavior of a stock's price is rich of information concerning its future predictability. Thus, many researchers repeat the conjecture that "*patterns*" of past price behavior will tend to happen repeatedly in the future. On the other hand, the theory of random walks, developed by famous mathematicians, is used by some economists to
10 show that the stock's future price path is no more predictable than the path of a series of cumulated random numbers. In simple words, the past cannot be used to predict the future in any meaningful way.

In the direction of random walk, in 1900, the French mathematician Louis Bachelier [3] initiated a new chapter in the financial literature by proposing, however in
15 a rather ambiguous way, that security prices appear to follow a stationary Gaussian random walk, and therefore price changes are uncorrelated. Many decades later, Bachelier's suggestion has been supported in a more explicit way by Osborn's work [41], where he has shown that the change of logarithm of prices has the same properties as a particle in the Brownian motion.

The Gaussian hypothesis was seriously questioned by Mandelbrot [36, 37] who
20 observed that the implication of the *leptokurtosis* (i.e., its excessively peaked character) was neglected by the previous researchers, contrarily on what someone could observe in the empirical distribution of price changes. In another words, his findings suggested that the distribution of the logarithm of price changes is *not* Gaussian
25 but rather *stable* Paretian since outliers are actually more common than there would expect to be under the Gaussian distribution. Additionally, Mandelbrot [37] provided evidences that stock price series are not stationary, and there is a weak (linear or nonlinear) dependence in their changes. Although Fama [15, 16] concluded that stock price changes do follow a stable Paretian distribution, he insisted that daily
30 price increments are random, independent and not correlated.

Many years later, Lo and MacKinlay [33] tested the random walk hypothesis for weekly price changes data on an equal- and a value-weighted market indexes. For the entire period and for all subperiods, the rejection of the random walk hypothesis did not support a mean-reverting model of asset prices. Thus, they alleged that the
35 presence of heteroscedasticity was not able to explain completely the rejection of the random walk hypothesis. What is more, they found a positive serial correlation in

contrast with Fama and French [16], who observed a weakly negative autocorrelation in weekly stock price changes. The negative autocorrelation was appeared due to the slowly mean-reverting behavior of the stock price series while they also reported
40 that autocorrelation varied over time. Since then, a voluminous research has been conducted to confirm or reject the validity of the random walk hypothesis based on empirical data analysis.

This paper is inspired by results obtained in Cutler et al. [12], who demonstrated that about one third of the stock price changes in S&P500 can be attributed to the
45 arrival of macroeconomic and political news. Furthermore, despite the passage of time and the massive improvement in technology, Cutler's et al. [12] conclusion remained unchanged even though the size of unexplained market movements has grown incredibly, as Cornell [9] demonstrated recently. In this direction, we study how selective events in the course of time have affected the behaviour of S&P500
50 price-index using high frequency data for the time period between May 1996 and March 2016. Instead of just using tests to reject or confirm the random walk hypothesis, we take an advantage of the recently introduced Horizontal Visibility Graph method [34, 47] to identify the characteristics of the generating process of the index prices.

55 The main purpose of our study is to investigate whether crises have affected the behaviour of the index, and if so, to examine whether different types of crises had the same impact on the index. In this regards, using 5-min data and applying the rolling window with overlap method, we find that all major crises that took place the last twenty years have affected considerably the behaviour of the index. Moreover,
60 our results suggest that there exist certain patterns in the way that the index reacts to specific crisis events.

The remainder of the paper is structured as follows. In Section 2, we provide the literature review of the Horizontal Visibility Graph method which is the cornerstone of our study. In Section 3, the presentation of the data is provided. A detailed
65 analysis of the adapted methodology is given in Section 4. Empirical results and their analysis for the whole time period, and the irreversibility of the S&P 500 price-index are presented in Section 5. Section 6 concludes the whole discussion.

2. Network Theoretical Approach: Horizontal Visibility Graph

Network modeling is a novel and rapidly developing area of research in social sciences, economics and finance. Mantegna and his co-authors [7, 11, 24, 30, 38, 46] were the first who proposed that techniques and tools from network theory can be applied to uncover the true nature of the underlying structure of financial markets. Many more researchers have followed, see [2, 5, 6, 17, 23, 43–45] among numerous others.

In our paper, the *Horizontal Visibility Graph* (HVG) which was recently introduced by Luque et al. [34] is considered. The HVG algorithm belongs to the family of *visibility algorithms* (VG) proposed by Lacasa et al. [27], and uses the concept of visibility [13] to map time series into graphs according to a specific geometric criterion. In [27], it was shown that time series structure is inherited in the associated graph, such as periodicity, randomness, etc. Thus equivalently, one can extract useful information regarding the properties of the original series based on the analysis implemented in the associated graph.

The geometric criterion proposed for the HVG method is basically rather simple, see [34]. Let $\{X_i\}_{i=1,2,\dots,n}$ be a time series with n observations. Each point in the series is transformed into a node in the associated graph, and two arbitrary nodes i and j have visibility to each other, and hence they are adjacent in the associated graph, if:

$$x_i, x_j > x_n \text{ for every } n \text{ such that } i < n < j.$$

[Insert Figure 1 somewhere here]

For illustrative purposes, a graphical representation of the HVG method is shown in Fig. 1. In the upper part, there is a bar-chart of a periodic time series while in the lower part there is a depiction of the associated graph after having applied the HVG method to the original data. Based on Gutin et al. [18], we can emphasize two of the most significant properties of HVG:

1. The associated graph is always connected, since all data points in the series have visibility to the nearest neighbors (i.e., the previous and the following one).

2. The mapping process is invariant under any affine transformation of the original time series, i.e., we will end up with the same graph regardless of any axis rescaling of the initial series.

In the next subsections, the importance of the properties mentioned above for the analysis of financial data is explained.

2.1. Description of randomness and chaos

In [26, 34], it is shown that the associated graph of any uncorrelated stochastic (random) series, which is independent of the shape of the probability density function $f(x)$ (i.e., distribution-free), has the degree distribution of the form:

$$P(\kappa) = \frac{1}{3} \left(\frac{2}{3} \right)^{\kappa-2}, \quad (1)$$

where $\kappa \geq 2$ for series of infinite length. Easily, Eq. (1) can be rewritten as

$$P(\kappa) \sim \exp^{-\gamma\kappa}, \quad (2)$$

where in the case of uncorrelated stochastic series, $\gamma = \ln(3/2)$. For *correlated* stochastic process, the exponent $\gamma > \ln(3/2)$; higher values of γ correspond to stronger *autocorrelation* in the series. On the other hand, for series that derives from *chaotic* processes, the exponent $\gamma < \ln(3/2)$, and higher values of γ correspond to higher dimensions of the attractor.

[Insert Figure 2 somewhere here]

In Fig. 2, a graphical illustration of the degree distribution of the associated HVG for three different series, random, correlated stochastic and chaotic, is provided. Based on [26], the exponent γ can be calculated by fitting an exponential function to the tail of degree distribution of the associated graph. In the present paper, the exponent γ is calculated by fitting a linear function to the tail of the degree distribution in a semi-log scale. Numerical experiments in [26, 34] show that the HVG method is a reliable tool to distinct both noisy and high dimensional chaos from randomness (stochasticity).

2.2. Quantifying the degree of irreversibility of time series

A time series $S = \{x_1, x_2, \dots, x_n\}$ is called statistically time-reversible if $S^- = \{x_{(-1)}, x_{(-2)}, \dots, x_{(-n)}\}$ has the same joint distribution with S [48]. This merely implies that both S and S^- series are statistically equally probable, and consequently, any independent and identical distributed random variable is a reversible sequence. Using another definition, we can conclude that "*the probabilistic properties of reversible series are invariant with respect to time reversal*" [14], and that "*reversibility is shown to imply stationarity*" [29]. Based on the aforementioned definitions, nonstationary time series are always *irreversible*, and thus it is only meaningful to study time reversibility in stationary series. Stationary processes, such as the linear Gaussian random process, that exist at thermal equilibrium are reversible [28]. On contrary, stationary processes which contain underlying nonlinearities such as dissipative chaos, and other processes that exist out of thermal equilibrium are irreversible processes. In this regards, many researchers also claimed that time irreversibility is associated with the presence of nonlinearity, and in particular, Cox [10] claimed that "*irreversibility is the symptom of nonlinearity*". The HVG method can not only successfully discriminate between reversible and irreversible stationary time series, but it can also quantify the degree of time irreversibility for nonstationary time series [28]. Since the definition of a reversible series requires stationarity, by implementing the new concept of HVG reversibility here, we are also able to quantify the degree of time asymmetries in the underlying dynamics of a nonstationary time series. Based on this concept, a process is characterized as time reversible when both direction of time evolution seems "*right*" for a particular series.

Following [25], a dynamical process $\{X_t\}$ is said to be HVG stationary *if and only if* the topological properties of the HVG associated to a sample time series of size n extracted from $\{X_t\}$ are asymptotically (for large n) invariant under time shift (in the statistical sense). More specifically, let $S = \{x_1, x_2, \dots, x_n\}$ and $S' = \{x_{1+\tau}, x_{2+\tau}, \dots, x_{n+\tau}\}$ be two sample series extracted from $\{X_t\}$. The degree distributions of HVG associated to the sample series, S and S' , are asymptotically (for large n) identical for HVG stationary processes.

To be able to discriminate between reversible and irreversible time series, one has

to separate the degree of each node into κ_{in} and κ_{out} such that $\kappa(i) = \kappa_{in}(i) + \kappa_{out}(i)$, where $\kappa_{in}(i)$ is the number of nodes from the past which have visibility on a node i , and $\kappa_{out}(i)$ is the number of future nodes where a node i has visibility based on the HVG criterion. Hence, a process $\{X_t\}_{t=1,2,\dots,n}$ is assumed to be HVG reversible *if and only if* the in-degree and the out-degree distributions of the associated HVG are *asymptotically identical* for large values of n . For series of finite size, we can quantify the degree of irreversibility of a process by calculating the divergence between the in- and out- degree distributions of the associate HVG. The higher the distance between the two distributions is, the more irreversible a process is.

In our study, instead of employing the Kullback-Leibler divergence for calculating the divergence between the in- and out- degree distribution of the HVG as originally proposed in [28], we recruit the Hellinger distance [20], which does not introduce any bias for time series of finite length [31]. The Hellinger distance between two discrete probability distributions $P(p_1, p_2, \dots, p_n)$ and $Q(q_1, q_1, \dots, q_n)$ is given by:

$$H(P, Q) = \frac{1}{\sqrt{2}} \sqrt{\sum_{i=1}^n (\sqrt{p_i} - \sqrt{q_i})^2}. \quad (3)$$

The value of Hellinger distance should be zero for HVG reversible process of infinite size. However, given the fact that all real life time series are finite, it is possible to face the situation where a reversible series has $H \neq 0$ yet, as the size of the series increases $H \rightarrow 0$ asymptotically. If a series is an irreversible one, then, as the size of the series increases, $H \rightarrow h$ asymptotically, where $h > 0$. In Fig. 3, we plot the in- and out- degree distribution of a reversible and an irreversible process. In the first case, although the two distributions are very close to each other, they are not identical and this can be attributed to the finite length of the series. For the irreversible process, the divergence between the distributions is obvious.

[Insert Figure 3 somewhere here]

3. Data

Our base dataset consists of tick data from Thompson Reuters Tick History (TRTH) for the S&P500 price-index that starts on the May, 3rd, 1996 to March,

180 3rd, 2016. Since higher frequency inevitably leads to a larger microstructure noise, we, as it has been suggested by Hansen and Lunde [19], initially aggregate the data and construct a dataset that contains 440,000 observations of 5-minute data points, see also arguments in [32]. In the Fig. 4, we plot the daily closing prices of the index for the corresponding time interval. It is very common in economics and finance to
 185 exploit the properties of logarithms, and instead of analysing the original data set, to work with the logarithm of the data. As it is already mentioned in Section 2, HVG method is invariant under axis transformation, and as a direct consequence, both time series, i.e., with original prices and with log-prices, generate the same HVG graph.

190 [Insert Figure 4 somewhere here]

4. Methodology

In the present paper, the question on how particular crises that occurred during the last 20 years affected the behavior of the S&P500 is considered. In this regards, we split our initial dataset into shorter periods of study to identify possible changes
 195 in the US market behavior. Moreover, in order to achieve continuity in our results, the method of rolling window with overlap is applied. Particularly, the length of each window is 5,800 observations (or 71 trading days), and the overlap between two consecutive windows is 3,900 observations (or 48 trading days). In total, we create 229 subperiods of interest, and each and every subperiod is transformed into
 200 a graph by using the HVG method. For every window, the exponent γ of the degree distribution, Eq. (2) is calculated as well as the Hellinger distance between the in- and out- degree distribution of the associate network, Eq. (3). Throughout this process, the properties of the series can be identified, i.e., if the series is correlated (or uncorrelated) stochastic or chaotic, and the degree of irreversibility of each sub-
 205 period can be quantified as well. Finally, whether the behavior of the sub-series has changed during the periods of crisis is examined, and whether the reaction of the market is the same for all crisis events is tested. For the better understanding of the empirical part, in Table 1 six major crises that occurred throughout the whole

time-period of observations are reported.¹

210

[Insert Table 1 somewhere here]

5. Empirical analysis

In this section, the results obtained for S&P500 by implementing the aforementioned HVG method are presented and discussed. The section is divided into two subsections. In the first part, the behavior of the market is analyzed for the whole
 215 studied period as well as for Subperiods 1 to 6 paying particularly attention on how crises affected the S&P 500 price-index. In the second part, whether S&P 500 price-index is a time reversible series, and how crises affected the degree of irreversibility of the index in the course of time are investigated.

5.1. S&P 500 index series all over the period 1996–2016

220 After mapping the observations of S&P 500 price-index time series in a graph through the HVG method, we are in a position to extract the degree distribution of the associated graph, and we calculate the value of the exponent γ , see Eq. (2), which is 0.026 for the whole time interval starting from 3rd May 1996 to 3rd March 2016. In Fig. 5, the degree distribution of the associate graph of the index series is
 225 plotted.² The exponent γ equals the slope of the tail of the degree distribution in a semi-log plot.

[Insert Figure 5 somewhere here]

The fact that the value of exponent γ is less than $\ln(3/2)$ means that the S&P500 price-index series appears to exhibit a chaotic behavior, and more specifically, it has
 230 similar properties with a low dimensional chaotic process. Numerous literature exist

¹Since by the end of February 2014 four out of five European countries that had asked for a bailout programme accessed again the private debt market, we assume that the European debt crisis (see Subperiod 4) is over.

²As a minor remark we should mention here that there is a node with extreme degree of 1,750, which has not been included in Fig. 5 for visualization arguments. However, the analysis conducted for the exponent γ considers also that extreme value.

providing weak evidences that stock price series behave similar to a chaotic process and the existence of long term dependences can be confirmed within stock price series [8, 22, 40, 42]. However, the existing statistical tests cannot accurately infer whether a series is indeed chaotic or random. Our finding does not contradict, but
235 rather verifies and reasonably explains what other researchers have found using other methods.

The results obtained reveal that a deterministic nonlinear structure underlies the S&P500 high-frequency data. This outcome explains why many researchers traced a nonlinear dependence in stock price series, yet they were uncertain for the source
240 of this nonlinear structure [35]. Thus, the existence of chaos might convincingly explain the nonlinear dependencies derived in financial time series. However, there are contradicting studies which exclude the existence of chaotic behavior as a source of nonlinearity [1, 21, 39].

The most important implication of the chaotic behavior is that stock prices
245 appear to be predictable to some extent. However, the horizon where we can successfully predict the future trajectories can be better determined by calculating the Lyapunov Exponents. Even though a chaotic process is indistinguishable from the unpredictability, due to the sensitivity issues in the initial conditions, a chaotic system is predictable for a limited time span and then its behavior is seemingly random.
250 Despite its phenomenal randomness, any chaotic system does contain a deterministic structure. In addition, in classical thermodynamics chaos exists in dynamical systems that operate out of equilibrium and are characterized by entropy production. Pro rata, as the equity market behaves similar to chaos, it is a dynamic system that continuously operates out of equilibrium. Thus, S&P 500 price-index can be
255 seen as a non-isolated system where the outer environment interrupts its way to equilibrium by introducing external turbulence in the system and causing entropy production.

Although we just reported that the S&P 500 price-index series behaves similar to a chaotic process over the last 20 years time period using high frequency data,
260 the purpose of this research is to investigate how the behavior of the index varies over time.

[Insert Figure 6 somewhere here]

In Fig. 6, we can observe the values of exponent γ for all distinct time-windows. At this point, we should mention that each *dot* represents a different window of our initial dataset, and dots are located on the x -axis based on the date of the first observation in each window.³ The *red line* denotes the point where γ exponent equals $\ln(3/2)$, which corresponds to an uncorrelated stochastic process. *Red shadowed areas* indicate periods of crises which have been endogenously created by the market forces, i.e., large drop in stock prices following a price bubble. On the other side, *grey shadowed areas* represent periods of crises when the crisis occurred either in the US economic/political reality or abroad. Consequently, Dot.com bubble collapse (2000) and US subprime crisis (2007) are denoted in the graph with red color while all the other crisis events are denoted by grey color.

With a glance on Fig. 6, it is easily discernible that in the grey shadowed areas there are valleys of the γ exponent in the chaotic band, a fact which is not true in the red shadowed areas. In Table 2, a summary of the market behavior is reported during the periods considered. However, since our major concern is to study the behavior of the market during periods of crisis, in Table 3, we also report the ratio of windows that exhibit a particular behavior and coincide with a crisis event.

[Insert Table 2 somewhere here]

[Insert Table 3 somewhere here]

What we can infer from Table 2 is that mainly chaotic behavior emerges when a crisis is ongoing, while correlated stochastic behavior is more common when there is no an ongoing crisis. About 83.18% (or 94 out of 113) of windows that coincide with tranquil periods appear to behave similar to a correlated stochastic process.⁴ When a crisis is ongoing, almost 50% of the periods (windows) appear to behave similar

³For example, the first window covers the period from 3rd May to 8th August 1996 and the corresponding dot is located on the x -axis at the point 3rd May 1996.

⁴We do not make any comment regarding the uncorrelated stochastic behavior since it does not seem to be a repeated behavior that worth particular analysis.

to chaos and another 50% similar to a correlated stochastic process. An important aspect would be to investigate if there is any pattern in the behavior of the market during different types of crisis.

290 In Table 4, the set "crisis event" is partitioned into two non-overlapping sets; one group which contains crisis events that are created *endogenously* by the market forces, and another group with all the other crises that took place in the outer environment of the US equity market, i.e., crisis that raised either in the US economic and political reality or abroad.

295 [Insert Table 4 somewhere here]

Results in Table 4 indicate that chaotic behavior rises when a crisis occurs in the outer environment of the market, while the properties of the S&P 500 price-index are similar to a correlated stochastic process, when the crisis has been created endogenously by the market dynamics. In total, 86.95% (or 40 out of 46) of the
300 windows that coincide with an internally created crisis by the markets' forces behave similar to a correlated stochastic process, while 91.2% (or 52 out of 57) of windows that coincide with crises happened in the US economic and political reality or abroad behave similar to a chaotic process.

Those findings reveal some very interesting aspects of the US market behavior. Bearing in mind that almost 83% of the windows that coincide with tranquil periods
305 behave similar to a correlated stochastic process, and that around 87% of the windows that coincide with crisis events created internally by markets' dynamics, then we have some evidence to infer that these types of events do *not* alternate the behavior of the market at all. Additionally, it appears the behavior of the market does
310 not alternate when a bubble in stock price does inflate and deflate. Consequently, US market reacts in most cases, when an event happens in its outer environment, and exhibits a chaotic behavior. Consequently, as long as the existence of chaos is related to entropy production, and entropy is a measure of disorder, we can infer that events that take place in the outer environment of the market drive the system
315 out of equilibrium causing an increasing disorder in the system. For instance, let us have a close look in an event that happened at the end of 2003 and beginning

of 2004. As we can observe in Fig. 6, there is a rapid change in the behavior of the market similar to that of the Asian crisis in 1997, yet these windows are not shadowed by any color. At that time the Federal Reserve rose the interest rates, and at the same time oil reached its maximum price for the last 20 years. Although, there is no assurance for which of these events caused an alternation in markets' behavior or affected the market the most, we have a strong indication that our conclusion that chaotic behavior appears when an important event takes place in the outer environment of market is valid.

Before proceeding to the second part of this section, the analysis conducted so far reveals that the US market reacts only in the case that a crisis is ongoing either in the US political and economic reality or abroad, while equity market crises that follow a rapid stock price expansion do not alter the behavior of the market.

5.2. Irreversibility of S&P 500 price-index

In the previous subsection, we studied the behavior of the S&P500 price-index over the sample period of time and how particular events affect the index by calculating the γ exponent of Eq. (1). In this section, another property of the index series will be considered, and how the time irreversibility of the price-index series varies over the course of time is examined. As discussed in Section 2, this can be accomplished by calculating the Hellinger distance, H , between the in- and out-degree of the associate graph.

[Insert Figure 7 somewhere here]

In Fig. 7, the in- and out degree distributions of the directed HVG are plotted. What it is observed is that the two distributions do not coincide, and thus, we cannot allege that the series is a time reversible one. The calculated Hellinger distance between the two distributions is 0.0136, which is larger than zero verifying that the series is irreversible. We emphasise that given the large size of this series, the expected value of the Hellinger distance for a reversible series should be approximately zero. This result verifies what we derived in subsection 5.1, i.e., that the market behaves as a chaotic process, and it is true that any chaotic process is an irreversible one.

To be more precise, a time series of infinite length is time reversible if the in- and out- degree distribution of the associated graph coincide, which implies that H between the two distribution is zero. However, for reversible series of finite size
350 Hellinger distance is not exactly zero yet the value of H approaches asymptotically zero as the length of a series tends to infinity. The challenged we faced at that point is that, to the best of our knowledge, there is no benchmark value available for H that separates reversible and irreversible series of finite size. Nevertheless, after having performed the Augmented Dickey-Fuller root tests [4], we found that
355 only 18 out of 229 subseries are stationary with confidence 99%. This implies that we do not actually examine whether subseries is time reversible, but rather, how irreversible it is and how crisis affects time asymmetries. For clarity, we mention that a nonstationary process is always time irreversible.

In Fig. 8, we plot the values of the Hellinger distance for all windows. We
360 observe that none of the values is close to zero which verifies that all subseries are irreversible. This finding is in line with [18, 27] where it is stated that financial series are in principal irreversible. After all, it would be unexpected to find reversibility in our results given that "*time irreversibility is the rule rather the exception when it comes to nonlinearity*" [26], and we just show that S&P 500 index behaves similar to
365 a chaotic process. Interestingly, the irreversibility of the index varies over time considerably. Within the red shadowed areas, we observe that H fluctuates at a lower level in comparison with the white and grey regions. Exceptions are two windows at the end of 2001 where H peaks. These windows coincide with the 9/11 terrorist attacks, a major event in the recent US history that affected considerably the prop-
370 erties of the S&P 500 index series. On the other hand, within the grey shadowed areas, H fluctuates at higher level in comparison with the red shadowed. This is especially visibly during the European debt crisis and Chinese equity market crash. Tumminello et al. [46] have found a link between the degree of time irreversibility of a process, and its amount of entropy production. The more irreversible a process is,
375 the higher the production of entropy of the system is. Thus, we can infer that grey shadowed regions are periods when the market is more disordered in comparison to tranquil periods and periods of endogenously created by the markets' dynamics

crisis.

What is more, increasing irreversibility denotes also increasing time asymmetry.
380 Two of the most important asymmetries that underlie financial transactions are asymmetry in investors beliefs and information. Even though we cannot claim which kind of asymmetry is affected more by the existence of a crisis, we can allege that these types of crises increase asymmetries within the market.

Finally, the fact that red shadowed areas have a lower degree of time irreversibility
385 ity denote less disorder in the market throughout the corresponding time interval. This might be as a contradiction with what we proposed in the subsection 5.1 observing that the behavior of the index remains the same during tranquil periods and periods where an endogenously created by the markets' dynamics crisis takes place. However, economists characterise these types of crises as a correction movement on
390 behalf of markets' participants after a prolonged inefficiency of the market. Thus, this behavior is not unexpected.

[Insert Figure 8 somewhere here]

6. Conclusions

In this paper, we recruit the recently introduced HVG method to analyze high
395 frequency (5-min) US stock market data, and examine the behavior of the S&P 500 price-index series from May 1996 to March 2016, and investigate how different kinds of crises affect the behavior of the market.

Our findings provide strong evidence that behavior in the S&P 500 price-index series is chaotic, which means that the stock series has an underlying deterministic
400 structure, yet a nonlinear one, and thus it is unpredictable. The fact that the index series for the whole time interval is an irreversible process provides even more support to our argument.

Since the main goal of our approach is to analyze the behavior of the index series throughout periods of crises, we decompose the initial series into six subperiods, and
405 we examine the behavior of each particular subperiod. For the sake of continuity in our results, the rolling window with overlap method is implemented where the

length of each window is 71 trading days, and the overlap between two consecutive windows is 48 trading days.

We found that the behavior of the market during tranquil periods as well as
410 during periods of endogenously created by the market dynamics crises, i.e., large
drop in stock price following a bubble in the stock prices, is similar to a correlated
stochastic process with strong autocorrelation among prices. On the other hand,
when a crisis happens in the outer environment of the market i.e., either in the US
economic and political reality or abroad, then, the stock price series behaves similar
415 to a chaotic process. In other words, when a bubble in the stock prices burst it does
not affect particularly the behavior of the index, while changes in the state of the
economy or politics of the country or abroad drive the market out of equilibrium
and increases the disorder in the system.

Similar conclusions can be derived after examining how irreversibility of series
420 evolve over the course of time. The impact of an external crisis affects the market
considerably, and the degree of irreversibility reaches its maximum values which
means that the disorder in the market is high since a link between irreversibility
and entropy production exists. On contrary, when a market experiencing a stock
price bubble burst, the irreversibility fluctuates at low levels indicating the disorder
425 in the system is generally much less than any other period.

Finally, the most important conclusion is that since none of the subseries seems
to be reversible, and consequently the market increases its entropy, the market never
reaches equilibrium and remain in a disorder state constantly.

430 **Acknowledgement:** This paper benefited from the comments of participants at
the 2016 Financial Risk & Network Theory seminar, Cambridge, UK, the 3rd Quan-
titative Finance and Risk Analysis (QFRA2017) Symposium, Corfu, Greece and the
13th Econophysics colloquium & 9th Polish Symposium on Physics in Economy and
Social Sciences (EC & FENS 2017), Warsaw, Poland as well seminar talks in the Uni-
435 versity of Liverpool (UK) and Shanghai University (China). Warm thanks are due
to our EPSRC/ESRC CDT industrial and academic partners, Dr Kimmo Soramäki
(FNA, UK) and Dr Eugene Neduv (Columbia University, US) who commented on a

preliminary version of our paper and who have afforded us considerable assistance in enhancing both the quality of the findings and the clarity of their presentation.

Tables

Subperiods	Time periods
Subperiod 1 (Asian & Russian crisis):	July 1997 - December 1998
Subperiod 2 (Dot.com bubble collapse):	March 2000 - November 2002
Subperiod 3 (USA subprime crisis):	September 2007- January 2009
Subperiod 4 (European debt crisis):	October 2009- February 2014
Subperiod 5 (Chinese stock market crash, Face I)	June 2015- September 2015
Subperiod 6 (Chinese stock market crash, Face II)	January 2016- March 2016

Table 1: Subperiods with the six major crises considered.

	Chaos	Uncorrelated stochastic	Correlated stochastic
No of windows	75 (32.75%)	2 (0.87%)	152 (66.38%)

Table 2: Number (ratio) of windows where exponent γ lies in the corresponding band

	Chaos	Uncorrelated stochastic	Correlated stochastic	Total
Crisis Event	57 (76%)	1 (50%)	58 (38.15%)	116
Tranquil period	18 (24%)	1 (50%)	94 (61.85%)	113
Total	75	2	152	229

Table 3: Number (ratio) of windows where exponent γ lies in the corresponding band during periods of crisis and during tranquil periods.

	Chaos	Uncorrelated stochastic	Correlated stochastic
Endogenous crises	5 (8.8%)	1 (100%)	40 (68.96%)
Exogenous crises	52 (91.2%)	0 (0%)	18 (31.04%)

Table 4: Number (ratio) of windows where exponent γ lies in a particular band and coincide with a particular type of crisis event, i.e., crises endogenously created by the market or crises in the outer environment of the market.

Figures

Figure 1: Graphical illustration of the Horizontal Visibility Graph algorithm. On the top we plot a periodic time series while at the bottom there is a graphical representation of the associated network.

Figure 2: Degree distribution of (from left to right) (a) random process, (b) chaotic process, (c) correlated stochastic process. The length of each series is $2 \cdot 10^4$.

Figure 3: The in- and out- degree distributions of an irreversible process (left) and a reversible process (right). The reversible series is a sequence of a random numbers drawn from the uniform distribution on $[0, 1]$ while the irreversible series is a sequence of numbers generated by the logistic equation with $\mu = 4$. The length of both series is $N = 2 \cdot 10^4$.

Figure 4: S& P 500 price-index series from 3rd May 1996 to 3rd March 2016. The red shadowed areas denote periods of sovereign crisis in USA while the grey shadowed areas denote crisis that took place abroad.

Figure 5: Semi-log plot of the degree distribution of the HVG of the S&P500 price-index from 1996 to 2016.

Figure 6: Values of exponent γ for all windows for the S&P 500 price-index. In the vertical axis it is plotted values of γ exponent and on the horizontal line we plot the first date of each window. The red line represents the value $\gamma = \ln(3/2)$ which correspond to an uncorrelated random process. Red shadowed regions represent periods of market crashes following a US market bubble, and grey shadowed regions represents periods of crisis that took place in the economic/political reality of USA or abroad.

Figure 7: The in-degree and out-degree distributions of the associated directed HVG of the S&P price-index from 1996 to 2016. Blue cycles represent the in-degree distribution and black cycles the out-degree distribution.

Figure 8: Values of Hellinger distance for all windows of the S&P 500 price-index. In the vertical axis, the Hellinger distance values are plotted, and on the horizontal line we plot the first date of each window. Red shadowed regions represent periods of market crashes following a market bubble in USA and grey shadowed regions represents periods of crisis that took place in the economic/political reality of USA or abroad.
